Abstract

Contrary to traumatic and iatrogenic intraabdominal hemorrhages, spontaneous intraabdominal hemorrhage is a challenging clinical situation. A variety of neoplastic and non-neoplastic conditions may cause spontaneous intraabdominal bleeding. Imaging findings vary depending on the source of bleeding and the underlying cause. In this article, we aim to increase the awareness of imagers to the most common causes of spontaneous intraabdominal hemorrhage by using representative cases.

Keywords Abdominal cavity · Adrenal gland neoplasms · Hemorrhage · Gastrointestinal tract · Gynecologic neoplasms · Kidney neoplasms · Liver neoplasms · Pancreas neoplasms · Retroperitoneal space · Spleen neoplasms

Introduction

Spontaneous intraabdominal hemorrhage due to neoplastic and non-neoplastic diseases is a challenging clinical situation as majority of the cases present with nonspecific symptoms, such as abdominal pain, hypotension, vomiting, and malaise. In rare cases, spontaneous intraabdominal bleeding may be the presenting manifestation. As the symptoms are nonspecific, imaging plays a crucial role in diagnosing and

triaging these patients. However, detection of the source of hemorrhage may be challenging in imaging studies due to massive hemoperitoneum. Nevertheless, some imaging findings may indicate the anatomic site of hemorrhage, such as ‘sentinel clot’ sign on computed tomography (CT). Sentinel clot sign is described as the highest attenuation hematoma adjacent to the bleeding organ. Furthermore, the underlying cause of hemorrhage (neoplasms or non-neoplastic diseases) may not be accurately detected in the initial stage. The detection and diagnosis of a causative tumor may not be evident in imaging studies due to the large hematoma [1, 2]. As prompt and proper imaging plays such a fundamental role in clinical management, we aimed to review the expected imaging findings of these patients in this article. We also made a detailed literature search to summarize the radiological findings of these cases (Tables 1, 2) [3–73].

rates of viral hepatitis and nonalcoholic steatohepatitis [4]. Radiological diagnosis of a typical HCC is relatively straightforward with multiphase contrast-enhanced CT or magnetic resonance imaging (MRI). The Liver Imaging Reporting and Data System (LI-RADS), providing standardized terminology for imaging findings in liver lesions in patients at risk of HCC, suggests dividing lesions into five categories (LR 1–5) according to suspicious imaging findings. Major features of CT/MRI LI-RADS include non-rim arterial phase hyperenhancement, nonperipheral washout, enhancing capsule, size, and threshold growth. A typical HCC is scored as LR-5 and demonstrates non-rim arterial phase hyperenhancement with nonperipheral washout on portal venous and delayed phases [74]. On liver MRI studies using hepatocyte-specific contrast agent (gadoxetic acid), they mostly appear hypointense on hepatobiliary phase (HBP) images. In patients with these characteristic imaging features, the diagnosis of HCC may be firmly made in a noninvasive manner without any need for histopathologic confirmation [3, 4].

Despite the fact that spontaneous rupture of HCC is not common, it is a potentially life-threatening complication. It is the third leading cause of HCC-related death after tumor progression and liver failure. It is observed in 3–15% of patients, with a lower incidence reported in Western countries compared to Asian countries. The exact mechanism of spontaneous rupture is unclear and does not appear to correlate with tumor size. Spontaneous rupture appears to be more common in subcapsular tumors which are not fully covered by liver parenchyma [5, 6]. Intense tumor vascularity and parenchymal necrosis within the tumor, portal vein, or hepatic vein thrombosis are mentioned among inciting factors for spontaneous tumor rupture [7, 8]. The history of transarterial chemoembolization may also be counted among potential risk factors [9]. The clinical symptomatology appears to be related to the tumor location within liver parenchyma. Hemoperitoneum and hemodynamic instability are more common in peripherally located tumors, whereas rupture of the tumor deeply located within hepatic parenchyma may present with right upper quadrant pain or may even be asymptomatic [5–8]. CT is the imaging modality of choice in patients with hemodynamic instability when HCC rupture is suspected due to its wider availability and faster acquisition time. The detection of hemoperitoneum, perihepatic, or subcapsular hematoma, extravasation of contrast material, and focal discontinuity of the tumor capsule (enucleation sign) are suggestive imaging findings for tumor rupture (Fig. 1) [7, 8]. Emergent transarterial embolization of the tumor is the most common treatment approach in patients with active bleeding. Surgery may be considered in patients who are not responding to transarterial embolization [5, 6].

Fig. 1 40-year-old male patient with known HCC presents with right upper quadrant pain. **A** Coronal postcontrast CT image shows a large mass (arrows) almost completely replacing the right liver lobe. Focal discontinuity of the capsule (curved arrow), intraperitoneal clot (arrowhead), and pelvic fluid (star) suggest tumor rupture. **B** Axial postcontrast CT image demonstrates subcapsular hematoma (asterisk) and focal discontinuity of the capsule (curved arrow). **C** Axial pre-contrast T1W fat-saturated MR image shows internal hyperintensity of the mass suggestive intratumoral hemorrhage (arrowheads)

Hemangioma

Hemangiomas are the most common benign hepatic tumors with an estimated prevalence of 20% [10]. In the majority of the cases, hemangiomas are usually small sized (<3 cm) and diagnosed incidentally. But, larger hemangiomas (>4–5 cm), also known as cavernous or giant hemangiomas, may present nonspecific symptoms related to capsular distension, biliary obstruction, thrombosis, infarction, or gastric outlet obstruction. On imaging, hemangiomas are usually well-defined lesions. Hemangiomatosis, in which the boundary of the lesion is ill defined, is a rare condition characterized by diffuse replacement of liver parenchyma with hemangiomatous lesions. It usually occurs in infants and may present with palpable abdominal mass and high-output cardiac failure [10, 11].

Spontaneous rupture is an infrequent and potentially life-threatening complication of hemangioma with a high mortality rate of 35%. The risk of rupture is strongly correlated with size of the lesion and subcapsular location [10, 11]. Intratumoral bleeding is also rare. The interval enlargement of the lesion and increased echogenicity at ultrasound (US) are suggestive features for intratumoral bleeding. Increased density at unenhanced CT and high signal intensity at T1-weighted (T1W) MR images are other imaging features of intratumoral bleeding [12]. In case of rupture, hemoperitoneum and intraperitoneal clot formations are typically observed on imaging [11]. In these patients, the detection of a liver lesion with characteristic imaging features of a hemangioma is mostly diagnostic [10]. Conservative therapy, hepatic artery embolization, hepatic artery

ligation, and resection are treatment options for hemorrhagic hemangioma [11].

Focal nodular hyperplasia

Focal nodular hyperplasia (FNH) is the most commonly detected benign liver mass after hemangioma and is reported to be found in 3% of the population, with a female predominance [12]. The vast majority of FNHs are incidentally detected small-sized lesions. Unlike hepatocellular adenoma (HCA), hemorrhage, and rupture are rarely seen in FNH with only anecdotal case reports [13]. In patients with hemorrhagic FNHs, the diagnosis may be challenging with imaging. MRI using hepatocyte-specific contrast agent is usually the preferred method for differentiating FNH from HCA and other liver tumors. Arterial phase postcontrast T1W images are critical for diagnosis as they may be hardly discernible on T2-weighted (T2W) and other pre- and postcontrast T1W images (Fig. 2). The presence of a so-called T2-hyperintense “central scar” is also another suggestive feature of FNH. The enhancement of this central area on the delayed phases of dynamic contrast-enhanced images is also helpful. HBP imaging is probably the most important phase for diagnosis. In this phase, FNHs appear isointense or hyperintense, as they contain mature hepatocytes, in contrast to HCAs, where they mostly appear hypointense [12, 14].

Hepatic metastases

Metastatic disease is the most common malignancy of the liver. The colon, breast, stomach, pancreas, and lung

Fig. 2 37-year-old female patient with known breast cancer underwent abdominal MRI examination for staging. **A** Axial T2W MR image shows a heterogeneous mass (arrows) in the left liver lobe. **B** Post-contrast arterial phase T1W MR image demonstrates hypervascular nature of the mass (arrows). **C** The mass is isointense on the hepatobiliary phase (arrows). **D** Axial precontrast T1W image shows a hemorrhagic focus (arrowhead) within the lesion. Imaging findings were found to be consistent with FNH. Follow-up studies confirmed stability of this lesion

are the most common sources for liver metastases. While metastases are usually seen as multiple discrete lesions, they may also be observed as solitary lesions [15, 16]. In the imaging literature, metastases are broadly categorized as hypo- or hyperenhancing. Hyperenhancing liver metastases typically originate from neuroendocrine tumors (NETs), renal cell carcinoma (RCC), thyroid carcinoma, breast carcinoma, choriocarcinoma, melanoma, and sarcomas [12]. Hypoenhancing liver metastases are predominantly supplied by portal venous branches and, therefore, appear more conspicuous on portal venous phase images. In contrast, hyperenhancing metastases show significant contrast enhancement during the arterial phase due to their abundant arterial blood supply [14–16]. Both hypo- and hyperenhancing tumors have been reported to bleed

spontaneously. There are no clear, established criteria outlining the risks of spontaneous bleeding in liver metastases [2, 12]. Metastases from lung tumors, RCCs, and melanomas are the most commonly reported types of liver metastases that spontaneously bleed [12]. Hemorrhagic metastases can demonstrate T1 hyperintensity on precontrast MR imaging (Fig. 3). However, this appearance should not be confused with metastases that have inherent T1 hyperintensity, such as metastases from melanomas (due to melanin content), colonic adenocarcinomas (due to coagulative necrosis), pancreatic mucinous cystadenocarcinomas (due to mucin), ovarian adenocarcinomas, and myelomas (due to protein) [15, 16]. Subcapsular hematomas may develop in patients with severe bleeding (Fig. 4) [12].

Fig. 3 54-year-old male patient with known metastatic small-bowel NET presents with right upper quadrant pain. **A** Axial T2W MR image shows large liver metastases (arrows) with T2-hypointense central zones (arrowheads), suggesting tumor hemorrhage. **B** Axial precontrast T1W MR image confirms the hemorrhagic components as hyperintense areas (arrowheads)

Fig. 4 30-year-old female patient with known synovial sarcoma presenting with acute abdominal pain. **A** Axial precontrast CT image shows multiple liver metastases. Focal discontinuity of the capsule (dashed arrows) around a subcapsular metastasis (arrow) and subcapsular liver hematoma (asterisk) with retracted clot (arrowhead)

are suggestive of tumor rupture. **B** Coronal postcontrast CT image demonstrates another subcapsular metastasis with discontinuity of the capsule (curved arrow). Hemoperitoneum is also present (star). The patient died immediately after this scan

Adenoma

HCA is a rare liver tumor with an estimated incidence of 4/100,000 with a prominent female preponderance. It is reported to be associated with use of oral contraceptives and anabolic androgenic steroids, glycogen storage disease, diabetes mellitus, and iron overload secondary to chronic transfusion therapy. HCAs are commonly seen as solitary lesions, but they are multiple in around 20% of the patients [12]. The correct diagnosis of the HCA is critical because of the potential risk for malignant transformation and spontaneous hemorrhage [2, 12, 17]. Hemorrhage is a common complication of HCA and may be observed in 25% of the cases. Most hemorrhages are intratumoral; however, intraparenchymal and subcapsular hematomas or hemoperitoneum may also be observed. Large tumors greater than 5 cm in size, exophytic location, and inflammatory subtype are potential risk factors for spontaneous hemorrhage [17, 18].

On MRI, typical imaging findings of HCAs include arterial hypervascularity with a subsequent isointense appearance on portal venous and delayed phases. Enhancing tumor capsule may be seen in a subgroup of patients [14]. HCAs may show foci of T1 hyperintensity due to the presence of fat or blood products (Fig. 5). Fat-suppressed or opposed phase T1W MR images can differentiate fat from hemorrhage [14]. Acute intratumoral hemorrhage may be hyperechoic on US and hyperdense on unenhanced CT. Old hemorrhages appear hypoechoic or cystic on US and heterogeneous hypodense on CT [17].

Hepatoblastoma

Hepatoblastomas, which arise from hepatocyte precursors, constitute the majority of malignant liver masses in infancy and childhood [19]. US is generally the first imaging method in a child with suspected liver mass because of its wider accessibility and better patient cooperation. MRI is also frequently preferred due to its high soft-tissue resolution and lack of ionizing radiation. On MRI, a typical hepatoblastoma is T1-hypointense, T2 heterogeneous hyperintense, heterogeneously enhancing mass that may contain hemorrhage and calcification [20]. Despite being rare, tumor rupture has been reported and is considered a poor prognostic factor for progression-free survival. Ascites, peritoneal nodules, and subcapsular hematoma may give rise to suspicion for tumor rupture [21].

Hepatic angiosarcoma

Hepatic angiosarcoma (HA), albeit rare, is the most common malignant mesenchymal tumor of the liver and accounts for 2% of all primary liver tumors [22, 23]. Exposure to thorotrast, vinyl chloride, arsenic, anabolic steroids, and radiation have all been mentioned in etiopathogenesis [2, 22, 23]. It is more common in males and mostly seen in the sixth or seventh decades of life. HAs are biologically very aggressive and often metastatic at the initial diagnosis. Lungs and spleen are the most common sites for metastases [2, 22]. On gross pathological evaluation, the tumor is characterized by remarkable necrosis and intratumoral bleeding [22, 23].

Fig. 5 24-year-old male patient with recently diagnosed Hodgkin lymphoma underwent an abdominal MRI exam. **A** Axial precontrast T1W fat-saturated MR image demonstrates a large mass (arrows) with internal hemorrhage (arrowhead) in the liver. The lesion shows peripheral enhancement on arterial phase (**B**) and is hypointense on HBP (**C**). Histopathological findings revealed hepatic adenoma. **D** Follow-up imaging study demonstrated the decrease in lesion size with a small residual hemorrhagic focus (arrowhead)

On CT studies, the tumor appears mostly hypodense on nonenhanced phase and hypoenhancing on postcontrast images. Unusual angiosarcomas may appear hyperenhancing tumors and mimic cavernous hemangiomas or other hypervascular tumors on single-phase imaging [22]. Multiphasic dynamic studies may be helpful to differentiate these HAs from hemangiomas or HCCs. On MRI, HAs are mostly hemorrhagic with heterogeneous internal enhancement (Fig. 6). Internal hyperintensity on precontrast T1W MR images and fluid–fluid levels on T2W images are highly suggestive for intratumoral bleeding [22]. Spontaneous tumor rupture is a potentially lethal complication of these tumors and may cause a significant amount of hemoperitoneum. Free tumor spillage into the peritoneal cavity after spontaneous

hemorrhage may also cause peritoneal angiosarcomatosis [24–26].

Non-neoplastic bleeding

Hepatic cyst

Hepatic cysts (HC) are among the most common benign liver lesions, with an estimated prevalence of 2.5% in the general population [27]. HCs may be solitary or multiple. Patients with multiple HCs should be evaluated for polycystic liver disease, typically associated with polycystic kidney disease. HCs are usually asymptomatic and incidentally diagnosed [27, 28].

Fig. 6 54-year-old male patient presenting with weight loss. **A** Axial postcontrast T1W MR image shows a heterogeneously enhancing large mass in the liver (arrows). **B** Axial precontrast T1W MR image demonstrates central large hemorrhagic component (dashed arrows). Histopathological confirmation revealed angiosarcoma

On imaging, HCs follow typical imaging characteristics of cysts elsewhere in the body. Intracystic hemorrhage is a rare complication of the HCs and may present with right upper quadrant pain. In this case, HCs may demonstrate heterogeneous hyperattenuation, fluid–fluid level, and internal septations on CT. On MRI, high signal intensity on pre-contrast T1W images and associating low signal intensity on T2W images are typical [2, 27, 28]. MRI studies with subtraction images may be helpful in these patients to differentiate HCs from cystic tumors, which may contain solid mural parts (Fig. 7).

Miscellaneous conditions

Although the most common cause of spontaneous hepatic hemorrhage in patients with cirrhosis is HCC rupture, spontaneous hepatic hemorrhage without malignant changes may also be rarely seen in cirrhosis. The underlying mechanism is either the rupture of macronodular cirrhosis or rupture of the lymphatic vessels and varicose veins due to portal hypertension [29]. Extreme caution should be exercised in these patients not to overlook an underlying HCC.

Pancreas

Neoplastic bleeding

Pancreatic cystic lesions have been frequently detected due to extensive use of cross-sectional imaging. A microcystic lesion in the pancreatic head may suggest serous cystadenoma (SC), whereas macrocystic lesions are more likely to be intraductal papillary mucinous neoplasms (IPMN) or mucinous cystadenomas. Although hemorrhagic intraparenchymal cysts are frequently observed in patients with acute and chronic pancreatitis, spontaneous bleeding has rarely been reported in SCs or IPMNs [30–33]. MRI is superior to other imaging modalities due to its unique soft-tissue resolution, which allows better evaluating the internal structure of SCs and pancreatic duct connection of IPMNs. Blood products typically give an inherent high T1 signal on MRI (Fig. 8).

Pancreatic NETs (pNETs) arising from islet cells constitute 8–10% of all pancreatic cancers [34]. Although sporadic neoplasms may occur, increased risk for pNET is well known in patients with multiple endocrine neoplasm type 1, von Hippel–Lindau, or neurofibromatosis type 1. On cross-sectional imaging, pNETs are usually hypervascular masses owing to their rich capillary network. Calcification, necrosis, hemorrhage, or cystic changes may be found in larger tumors [35, 36]. Hemorrhagic pNETs can be difficult to diagnose;

Fig. 7 Hemorrhagic liver cysts in two different patients. **A** 57-year-old female patient with known polycystic liver disease presenting with jaundice and recent-onset right upper quadrant pain. Axial T2W MR image shows multiple liver cysts and two cysts with internal fluid–fluid levels (arrowheads), suggestive of hemorrhage. **B** Axial precontrast T1W MR image demonstrates the hemorrhagic liver cysts (arrows) in the same patient as in **A**. **C–E** 50-year-old male

patient presenting with abdominal pain. **C** Axial fat-saturated T2W MR image shows a large hyperintense mass in the liver (arrows). **D** Axial precontrast T1W MR image demonstrates internal hyperintense foci suggestive of hemorrhage. **E** There is no enhancement on post-contrast T1W subtraction images. Imaging findings were found to be consistent with a hemorrhagic liver cyst. Follow-up imaging study demonstrated interval decrease in the lesion size (not shown)

Fig. 8 64-year-old female patient presenting with acute abdominal pain. **A** Coronal postcontrast CT image shows a multiloculated cystic lesion (arrows) in the pancreatic head. Also, note is made of central calcification (arrowhead). **B** Axial T2W MR image better revealed the multiloculated cystic nature of this lesion (arrows). **C** Axial fat-saturated precontrast T1W MR image demonstrates hemorrhagic component (star) of the lesion. Histopathological confirmation after surgical removal revealed hemorrhagic serous cystadenoma

Fig. 9 48-year-old female patient with known MEN-1 syndrome underwent MRI scanning. **A** Axial precontrast T1W MR image shows a hyperintense lesion (arrows) in the pancreatic head. **B** The lesion is hypointense (arrows) on fat-saturated T2W MR image. **C**

Axial postcontrast T1W MR image demonstrates peripheral enhancement of the lesion. A nodular enhancement (arrowhead) was also seen within the lesion. Imaging findings were suggestive of a hemorrhagic pNET. Surgical findings confirmed the diagnosis

however, dynamic contrast-enhanced MRI with subtraction images may be helpful by demonstrating the contrast-enhancing solid component or internal septae (Fig. 9).

Non-neoplastic bleeding

Non-neoplastic spontaneous bleeding of the pancreas is mainly related to pseudocysts and peripancreatic pseudoaneurysms, which are well-known complications of acute pancreatitis [36]. According to the revised Atlanta classification, any fluid collection seen 4 weeks after the onset of the disease is considered as a pseudocyst in patients with a history of interstitial edematous pancreatitis [37]. On imaging, a pseudocyst is an irregularly marginated or well-circumscribed cystic lesion depending on its stage. Blood products may be seen within

the lesion, which may cause T1 signal hyperintensity on MRI and high-attenuation on unenhanced CT [30].

Spontaneous rupture has also been described in some uncommon pancreatic lesions, such as pancreatic endometrioma [38]. In such lesions, hyperdense fluid or fluid–fluid level on unenhanced CT and high T1 signal intensity on MRI may be found, reflecting the hemorrhagic composition. A pancreatic lesion with peripancreatic or perisplenic hemorrhagic fluid collection may suggest tumor rupture; however, in such circumstances, preoperative diagnosis of the tumor type may be impossible (Fig. 10).

Fig. 10 38-year-old female patient presenting with acute onset epigastric pain. Axial postcontrast CT (A) and T2W MR (B) images show a cystic mass within the pancreatic tail (arrows) and associated subcapsular splenic fluid collection (arrowheads). C Axial precontrast T1W MR image delineates hemorrhagic nature of the lesion (arrows) and subcapsular splenic hematoma (arrowhead). D Axial postcontrast T1W MR image shows no apparent mural enhancement within the cyst. Histopathological findings after surgical extirpation revealed pancreatic endometrioma

Spleen

Neoplastic bleeding

The most common malignant tumors of the spleen are metastases, with hematopoietic tumors being the most common. Metastases from solid tumors are relatively uncommon. The most common solid tumors that metastasize to the spleen are melanoma, breast, lung, ovary, pancreas, and colon cancers. Metastases are usually hypodense on contrast-enhanced CT and hypointense on contrast-enhanced T1W MR images. Hemorrhage may be

detected in metastases from solid tumors such as RCC [39, 40].

The most common primary tumor of the spleen associated with hemorrhage is, although rare, angiosarcoma. Tumor rupture is not rare in these patients, with a reported prevalence of 25% [40]. Metastatic foci within liver parenchyma are commonly detected at the initial diagnosis. On cross-sectional imaging, these tumors are typically heterogeneously hyperenhancing masses with internal necrosis and hemorrhage. These imaging features characteristically reflect the biologically aggressive nature of these tumors. Perisplenic hematoma, hemoperitoneum, or intraperitoneal tumor spillage may occur as a consequence of tumor rupture

Fig. 11 42-year-old female patient with upper abdominal pain. A Axial T2W MR image shows multiple target-like lesions in the liver and spleen. Associating subcapsular fluid collections in the liver (arrows) and spleen (dashed arrow) suggest tumor rupture. B Axial

T1W MR image depicts hemorrhagic nature of lesions. Note the hyperintensity of the splenic subcapsular fluid collection (dashed arrow). Lesions were found to represent metastatic angiosarcoma of the spleen

(Fig. 11) [39–41]. Despite the fact that solitary or multiple splenic masses with concomitant liver metastases may also be detected in patients with metastases from different primary sources, the clinical history and internal features of the tumor may be helpful for diagnosis.

Non-neoplastic bleeding

Splenic epidermoid cysts (EC) are thought to be congenital lesions. The etiopathogenesis is related to fluid entrapment between the peritoneal mesothelial infoldings. It accounts for approximately 10% of all splenic cystic lesions and is mostly asymptomatic. On US, they are anechoic with low-level internal echoes reflecting cholesterol deposition. On CT or MRI, ECs follow the typical imaging characteristics of cysts detected elsewhere in the body [42]. Despite being rare, rupture of ECs may occur. A hemorrhagic lesion with associating subcapsular hematoma or hemoperitoneum may be detected on CT or MRI when rupture happens (Fig. 12). The absence of detectable enhancement in contrast-enhanced studies is usually sufficient in

differentiating ECs from other hemorrhagic splenic lesions [43, 44].

Spontaneous splenic rupture is an infrequent complication in patients with sickle cell anemia and patients on anticoagulation treatment. The potential underlying mechanism in sickle cell anemia is splenic infarct with subcapsular hemorrhage and subsequent rupture. These patients may be hemodynamically unstable, and CT is the preferred imaging modality for diagnosis. On CT, spontaneous splenic rupture is diagnosed with detection of a subcapsular hematoma or hemoperitoneum with accompanying intrasplenic infarcts (Figs. 13, 14) [45].

Fig. 12 44-year-old male patient presenting with acute left upper quadrant pain. On US, hypoechoic subcapsular fluid collection encircling the spleen and an intraparenchymal mass of heterogenous echotexture were found (not shown). Axial T2W (A) and precontrast fat-saturated T1W (B) MR images show subcapsular splenic hematoma (dashed arrows) and a hemorrhagic lesion (arrows) in the spleen. C

Coronal T2W MR image better demonstrates the continuity between the lesion (arrow) and subcapsular hematoma (dashed arrow). No discernible enhancement was detected on postcontrast-subtracted MR images (not shown). Surgical findings revealed the rupture of a splenic epidermoid cyst

Fig. 13 39-year-old male patient with known sickle cell anemia presenting with acute left upper quadrant pain. A Coronal postcontrast CT image shows subcapsular splenic fluid collection (arrow) and splenic infarction (curved arrow). B Axial postcontrast CT image better demonstrates subcapsular splenic fluid collection (arrows). Imaging findings were found to be consistent with spontaneous splenic rupture

Fig. 14 67-year-old female patient on chronic warfarin treatment presents with acute left upper quadrant pain. Laboratory evaluation revealed a significant increase in INR (higher than 10). **A** Coronal contrast-enhanced CT image shows a large subcapsular splenic hematoma (arrows). **B** Axial contrast-enhanced arterial phase CT image demonstrates the contrast media extravasation (arrowhead) consistent with active bleeding. **C** Extravasated contrast increased on venous phase (arrowhead)

Fig. 15 35-year-old male patient presenting with severe left upper quadrant pain. On US, a large perinephric hematoma was found in the left kidney (not shown). Coronal postcontrast CT image shows the large perinephric hematoma (arrow) and accompanying renal mass (dashed arrow). Also, note is made of multiple parenchymal nodules (arrowheads) in lung bases, suggestive of metastatic disease. Histopathological confirmation of a lung nodule revealed metastatic papillary RCC

Kidney

Neoplastic bleeding

Renal cell carcinoma

RCC is the most common malignant renal tumor, with clear cell carcinoma being the most common subtype. Also, RCC is the most common malignant renal neoplasm associated with intratumoral hemorrhage or perirenal hematoma (Fig. 15). In addition, hematuria may be observed in cases where the tumor extends into the renal pelvis (Fig. 16) [46–48]. The tumor subtype is not a good predictor of hemorrhage, as both clear cell RCC and papillary RCC, the most common subtypes, usually contain hemorrhagic areas. Also, unlike angiomyolipoma (AML), tumor size is not a reliable predictor for bleeding in RCCs. Rarely, an arteriovenous fistula may develop within larger tumors, which may increase the risk of spontaneous bleeding. Tumor thrombus in renal veins may also predispose the tumor to bleed due to increased intratumoral pressure [49].

Angiomyolipoma

AML is the most common solid benign renal tumor. Histopathologically, it consists of variable amounts of disorganized vessels, fat, and smooth muscle. Although the vast majority of AMLs occur sporadically, 20% of cases are associated with tuberous sclerosis. In these patients, AMLs tend to occur multiple and are larger in size. Imaging-based diagnosis is usually straightforward if macroscopic fat is

Fig. 16 54-year-old male patient presenting with acute gross hematuria underwent a CT urography examination. **A** Unenhanced CT image shows hyperdense content in the renal pelvis (arrow) reflecting blood products. **B** Coronal postcontrast CT image demonstrates an endophytic hypervascular mass (arrows) in lower pole of the left kidney. Note tumor extension into the collecting system (arrowhead). Histopathological confirmation after partial nephrectomy revealed clear cell RCC

Fig. 17 49-year-old female patient with a known solid mass in the left kidney underwent a CT examination for preoperative planning. Axial precontrast CT image revealed a mass (arrows) containing macroscopic fat (asterisk). An internal fluid–fluid level (arrowheads) was also present, suggestive of intratumoral hemorrhage. The lesion was found to be consistent with angiomyolipoma. Follow-up studies confirmed stability of this lesion

seen; however, lipid-poor AMLs may be difficult to differentiate from RCCs [46]. Spontaneous hemorrhage is a well-known complication of AMLs, commonly occurring in AMLs greater than 4 cm in size (Fig. 17). Pseudoaneurysm may develop within larger lesions due to increased blood flow, and a pseudoaneurysm greater than 5 mm in size tends to bleed spontaneously (Fig. 18) [50]. Hyperdensity and fluid–fluid level on unenhanced CT reflect the intral-lesional hemorrhage. Perirenal or retroperitoneal hematoma may occur when the lesion ruptures. CT angiography (CTA) is usually the preferred imaging modality in the acute setting. With CTA, both diagnosis and mapping of arterial anatomy are confidently made for planning the endovascular intervention.

Oncocytoma

Oncocytoma is the second most common benign renal neoplasm after AML (3–7% of all renal masses). On imaging, it is usually peripherally located, well-circumscribed, hypervascular solid mass. In approximately half of oncocytomas, a low signal intensity capsule, T2-hyperintense central scar, spoke-wheel enhancement pattern, or segmental enhancement inversion may be identified; however, these findings are not specific and may also be found in RCCs (particularly in the chromophobe subtype) [46, 48]. The imaging-based diagnosis of oncocytoma is usually difficult, and histopathological confirmation is almost always required to differentiate from RCC. The presence of hemorrhage, albeit rare, has been shown in oncocytomas, and this makes differential diagnosis even more challenging [48].

Non-neoplastic bleeding

Renal cyst

Renal cystic lesions are the most commonly encountered renal lesions. Bosniak classification is widely used to separate surgical cystic lesions from non-surgical ones and divides renal cystic lesions into four categories according to their malignancy risk [51]. Patients older than 50 years usually have at least one renal cyst, with Bosniak type 1 or 2 cysts being the most common. Patients are generally asymptomatic, but larger cysts may complicate with infection, hemorrhage, or rupture (Fig. 19). Hemorrhage is a more common complication in patients with polycystic kidney disease. Hemorrhagic cysts are included in Bosniak type 2 or type 2F according to their sizes and locations. A hyperattenuating lesion (> 20 HU) without imperceptible enhancement on CT is considered a hemorrhagic cyst [51, 52]. Fluid–fluid level within a cyst may suggest intracystic hemorrhage, particularly in a patient with acute flank pain.

Fig. 18 39-year-old male patient with known tuberous sclerosis and bilateral renal angiomyolipomas presenting with acute left upper quadrant pain. **A** Axial precontrast CT image showed a left kidney angiomyolipoma (arrows) with internal macroscopic fat (arrowhead). Note the hyperdense area within the tumor (asterisk) and perilesional fat stranding suggestive of acute hemorrhage. **B** Axial contrast-enhanced CT image shows a large pseudoaneurysm (arrows) within the lesion. **C** Digital subtraction angiography (DSA) again showed this pseudoaneurysm (arrows). **D** Superselective embolization of this pseudoaneurysm was performed

Fig. 19 60-year-old male patient with known colon cancer underwent an MRI examination for recent-onset moderate abdominal pain. **A** Axial precontrast T1W MRI image shows a hyperintense mass (arrows) in the left kidney. **B** The mass is heterogeneously

T2-hypointense (arrows). **C** There is no discernible enhancement on postcontrast T1W subtraction images. Imaging findings were found to represent a hemorrhagic renal cyst. Follow-up imaging studies demonstrated interval shrinkage of the lesion

Hematomas in the perirenal and other retroperitoneal planes may also be observed in certain patients with cyst rupture (Fig. 20). In such cases, it may be challenging to identify the kidney cyst as the culprit lesion as hematoma may obscure the underlying abnormality.

Coagulopathies

Spontaneous subepithelial hemorrhage, also known as Antopol–Goldman lesion, is an extremely rare cause of painful hematuria in patients with known hemophilia or on warfarin treatment [53]. Multiphase CT urography (CTU) is the preferred imaging approach in patients with hematuria. In

the unenhanced images of CTU, Antopol–Goldman lesions are seen as hyperdense mural thickening of the renal pelvis and the upper ureter. In patients with a large hematoma, centrally located hyperdense mass adjacent to the renal pelvis may be detected (Fig. 21). Contrary to TCC, Antopol–Goldman lesions do not demonstrate enhancement after contrast injection. Follow-up CT scans may be necessary to show complete resolution of the lesion after proper treatment [54].

Miscellaneous conditions

Wunderlich syndrome, first described in 1856, is a rare clinical event characterized by spontaneous renal hemorrhage into

Fig. 20 74-year-old male patient with known left renal cyst presenting with left upper quadrant pain. **A** Axial T2W MR image from a year ago shows the left renal cyst (arrow). **B** Coronal postcontrast image from the current CT study demonstrates a large perinephric hematoma (arrows) and associating retroperitoneal hematoma

(dashed arrows). Imaging findings were found to be compatible with acute cyst rupture. Follow-up imaging studies demonstrated complete resolution of the perinephric hematoma without an underlying mass (not shown)

Fig. 21 32-year old male patient with known Hemophilia A presenting with recent-onset painful gross hematuria underwent a CTU examination. **A** Axial precontrast CT image shows a hyperdense mass in the upper pole of the left kidney (arrow). **B** On the postcontrast CT image, the lesion (arrow) did not demonstrate any discernible

enhancement. Note the delayed urogram of left kidney. Imaging findings along with the patient's history were considered to represent sub-epithelial hemorrhage (Antopol–Goldman lesion). Follow-up studies demonstrated complete resolution of the lesion (not shown)

the perinephric or subcapsular space. A variety of underlying causes have been identified, including renal neoplasms, hypertension, diabetes mellitus, chronic kidney disease, infections, vasculopathy, and vasculitis. When renal neoplasms are excluded, other causes are extremely rare (Figs. 22, 23) [55, 56].

Bladder

Neoplastic bleeding

Bladder cancer is the most common primary malignant

Fig. 22 44-year-old male patient with known systemic lupus erythematosus presenting with generalized severe abdominal pain. **A** Coronal precontrast CT image shows a large retroperitoneal hematoma (asterisks). **B** Coronal postcontrast CT image demonstrates the contrast media extravasation within the hematoma (arrows) consist-

ent with active bleeding. **C** Digital subtraction angiography (DSA) depicted active bleeding from a renal artery branch (arrow). **D** Superselective embolization was performed with subsequent control of the bleeding

Fig. 23 80-year-old female patient hospitalized for pneumonia and subsequent septic shock underwent CTA for evaluating the cause of acute hemoglobin drop level. Axial arterial phase CT image shows contrast media extravasation into the collecting system of the left kidney (arrows) and perirenal fat stranding. Note the delayed corticomedullary phase of the left kidney

neoplasm of the urinary tract, with TCC being the most common subtype. It is more common in males and mostly seen in the sixth decade of life. Exposure to several chemicals, smoking, bladder stones, chronic infection, and pelvic radiation have all been mentioned in the etiopathogenesis of TCC. Patients usually present with gross painless hematuria [57, 58]. The presence of gross hematuria is a very concerning sign of a urinary neoplasm, and these patients usually undergo both cystoscopy and CTU examination. In addition to confirming bladder cancer, CTU also allows local staging and detection of distant metastases in the abdomen [57]. The presence of endocavitary bladder hematoma associated with the neoplastic lesion is a common finding in these patients (Fig. 24).

Non-neoplastic bleeding

Spontaneous bladder hematoma may be seen in patients with known bleeding diathesis or on anticoagulant therapy. Similar to patients with TCC, those patients also present with gross hematuria and usually undergo a CTU examination. The absence of enhancement and no obvious attachment to the bladder wall may help in differentiating hematomas from TCCs (Fig. 25). Also, mobility of the lesion in US may suggest hematoma [58]. Despite all these mentioned imaging findings, cystoscopic evaluation is almost always needed to rule out a small focus of TCC in these cases.

Adrenal gland

Neoplastic bleeding

Adrenal lesions are usually incidentally detected masses (incidentalomas) during imaging for other purposes. Most of incidentalomas are benign non-functioning adenomas and are easily diagnosed with adrenal CT protocols or chemical shift MRI. Several malignant lesions may also affect the adrenal gland, with metastases being the most common in adults [59]. Despite the fact that several benign and malignant diseases, including adenoma, metastases, neuroblastoma, adrenocortical carcinoma (ACC), pheochromocytoma, and lymphoma, have been reported as a cause for spontaneous hemorrhage, ACC appears to be most common among all these (Figs. 26, 27, 28) [59, 60]. The presence of contrast-enhancing solid portion, calcification, or FDG uptake within hematoma may suggest an underlying adrenal mass, but a definitive diagnosis may be difficult as the lesions may be similar in appearance.

Fig. 24 70-year-old male patient presenting with acute onset gross hematuria underwent a CTU examination. **A** Axial precontrast CT image shows hyperdense structure within the bladder lumen (dashed arrow), suggestive of hematoma. **B** Axial postcontrast CT image

demonstrates a contrast-enhancing mass in the posterior wall of the bladder (arrows) and accompanying bladder hematoma (dashed arrow). Histopathological examination after cystoscopy and biopsy revealed TCC

Fig. 25 70-year-old male patient on chronic warfarin treatment presenting with acute gross hematuria. **A** Axial unenhanced CT image shows hyperdense structure within the bladder lumen. Axial (**B**) and coronal (**C**) urographic phase images demonstrate a large mass within

the bladder lumen (arrows). There was no discernible enhancement of the bladder mass and no obvious attachment to the bladder wall. Imaging findings were suggestive of a hematoma. No mass was detected in the subsequent cystoscopy

Fig. 26 33-year-old female patient with known multiple endocrine neoplasia syndrome type 2B presenting with severe hypertension. **A** Axial postcontrast CT image shows a thick-walled cystic mass in the left adrenal gland (arrows). A fluid–fluid level (arrowhead) was also present due to intratumoral hemorrhage. **B** The fluid–fluid level

(arrowhead) is noted again on T2W MR image. **C** Axial precontrast T1W MR image shows the hemorrhagic mass as mostly hyperintense (arrows). Histopathological confirmation after surgical removal revealed hemorrhagic adrenal pheochromocytoma

Non-neoplastic bleeding

Adrenal gland is supplied by around 50–60 small arteries and drained by a few veins. This unique anatomy is thought to

make it prone to spontaneous bleeding [61]. Anticoagulant therapy, antiphospholipid antibody syndrome, and metabolic stress (such as neonatal stress, sepsis, hypotension) have all

Fig. 27 42-year-old female patient presenting with left upper quadrant pain. Coronal (A) and axial (B) unenhanced CT images show a large hematoma in the left adrenal region (arrows) and associated retroperitoneal hematoma (dashed arrow in A). The adrenal gland could not be visualized separately from this large hematoma. C Axial

arterial phase postcontrast CT image demonstrates contrast media extravasation consistent with active bleeding. Histopathological examination after emergency surgery confirmed adrenocortical carcinoma

Fig. 28 58-year-old male patient with known HCC. A Axial postcontrast CT image shows liver masses (dashed arrows) and right adrenal mass (arrows). The patient presented with severe, acute right upper quadrant pain 15 days after this CT scan. B Axial postcontrast CT

image showed interval enlargement of the adrenal lesion with a small focus of contrast media extravasation (arrowhead). Imaging findings were found to represent tumoral hemorrhage. Emergency surgery confirmed hemorrhagic metastatic HCC

been mentioned in the etiology of spontaneous adrenal bleeding. Idiopathic bleeding has also been reported [60].

On imaging, an adrenal hematoma is similar to hematomas elsewhere in the body (Fig. 29). In patients with spontaneous adrenal bleeding, great caution should be exercised to rule out an underlying mass. The absence of the contrast-enhancing component on dynamic contrast-enhanced MRI with subtraction images and no FDG-uptake within the hematoma may be helpful in the differential diagnosis. However, even in these cases, an underlying neoplastic process may not be definitely excluded, and follow-up imaging should be planned to confirm interval resolution.

Gastrointestinal tract

Neoplastic bleeding

Acute gastrointestinal (GI) bleeding is a common urgent condition that may be life-threatening. While the most common cause of acute upper GI bleeding (above the ligament of Treitz) is peptic ulcer, diverticulosis is the most common underlying reason for the lower GI system. GI system tumors usually present with anemia due to occult bleeding and are relatively less common causes of acute

Fig. 29 44-year-old male patient with no known past medical history presents with acute onset left upper quadrant pain. **A** Axial unenhanced CT image shows a hyperdense mass in the left adrenal gland (arrows) with associating periadrenal fat stranding. No discernible enhancement was seen on postcontrast images (not shown). The lesion represented either a ruptured mass or an idiopathic adrenal

hematoma. The patient was hemodynamically stable, and close imaging and clinical follow-up were concluded. **B** Axial T2W MR image four months after the initial presentation demonstrates almost complete regression of the hematoma (arrows) with no associated underlying mass

Fig. 30 48-year-old male patient presenting with hematochezia. **A** Axial post-contrast CT image shows diffuse wall thickening of the rectum (arrows) and contrast media extravasation into the lumen consistent with active bleeding (arrowheads). **B** DSA image shows active

bleeding from a branch of the inferior mesenteric artery (arrow). **C** Bleeding control was achieved by superselective embolization of the artery with detachable coils. Subsequent colonoscopic biopsy was confirmed rectal adenocarcinoma

GI bleeding. Patients with overt GI bleeding may present with hematemesis, melena, or hematochezia, depending on the bleeding site and severity [62]. CTA with unenhanced, arterial, and venous phases has been widely used in the clinical setting of acute GI bleeding to evaluate the underlying cause and location of the source. Active contrast extravasation from the site of bleeding is a very important and valuable finding as it is helpful to guide endovascular treatment planning. On precontrast images, intraluminal hematomas tend to appear hyperdense. In the arterial and venous phases, endoluminal contrast extravasation may be detected in patients with active bleeding (Fig. 30). Oral contrast use is mostly not preferred in these examinations,

as oral contrast may hinder the observation of active contrast extravasation.

Non-neoplastic bleeding

A variety of common and uncommon non-neoplastic causes of GI bleeding have been identified on CTA. GI angiodysplasias that consist of thin-walled blood vessels is an unusual cause for overt GI bleeding. GI angiodysplasias may be seen throughout the GI tract and tend to be multifocal; however, antimesenteric borders of the caecum and right-sided colon are the most common harboring sites. Imaging findings of active bleeding from angiodysplasias are similar to those

Fig. 31 75-year-old female patient presented with melena. She was hemodynamically stable. Upper and lower GI endoscopic studies were found to be unremarkable. An abdominal CTA was planned for assessment of the underlying cause. **A** Coronal arterial phase postcontrast CT image shows accumulation of vessels in the jejunum wall (arrow) suggestive of angiodysplasia. **B** DSA image demonstrates the angiodysplasia as disorganized ectatic vessels (arrow)

Fig. 32 73-year-old female patient on chronic warfarin treatment presents with abdominal pain. Laboratory evaluation revealed high levels of INR (higher than 10). Axial unenhanced CT image shows hyperdense mural thickening of the ileum (arrows) considered an intramural hematoma

of other causes, but the diagnosis is usually straightforward as they have distinct imaging features. The typical suggestive imaging findings on CTA are focal punctate areas of enhancement in the bowel wall with the early filling of an antimesenteric vein (Fig. 31) [63].

Patients on anticoagulant therapy may present with acute GI bleeding. Spontaneous intramural small-bowel hematomas may also be seen in overcoagulated patients with warfarin. These patients may present with abdominal pain or intestinal obstruction. Intraluminal or intramesenteric hemorrhage or hemorrhagic ascites may be other associating findings. In precontrast images of the CTA, detection of hyperdense mural thickening is a highly suggestive finding for intramural hematoma (Fig. 32) [64]. Despite being rare,

spontaneous intramural duodenal hematoma may associate with acute or chronic pancreatitis (Fig. 33) [65].

Gynecological causes

Neoplastic bleeding

Gynecologic malignancies are frequently encountered neoplasms in women, with endometrial carcinoma being the most common, followed by ovarian and cervical cancers. Hormonal, viral, or genetic factors are often associated with gynecological malignancies [66]. Endometrium and cervical cancers mostly present with abnormal vaginal bleeding, whereas ovarian cancer typically causes bloating, constipation, or pelvic pain. Although spontaneous intraabdominal bleeding appears to be rare in patients with gynecological malignancies, invasion of surrounding organs and erosion of vessels may cause intraperitoneal hemorrhage, hematuria, or GI bleeding (Fig. 34).

Non-neoplastic bleeding

Rupture of an ovarian cyst is the most common cause of spontaneous hemoperitoneum in women of reproductive age [1]. Rupture of an ovarian cyst usually presents with acute pelvic pain. On US, a hemorrhagic ovarian cyst is a thin-walled cyst with fluid–fluid level, low-level echoes, and internal septations. Retracting clot adhering to the cyst wall may mimic a nodule but has no blood flow on color Doppler imaging (Fig. 35). In women of childbearing age, ectopic pregnancy rupture should be considered in patients presenting with acute abdomen and hemoperitoneum. A serum beta-human chorionic gonadotropin level greater than 2000 IU, without any imaging evidence of intrauterine pregnancy, should be considered highly suspicious for ectopic

Fig. 33 53-year-old male patient with known chronic pancreatitis presented with recent-onset epigastric pain. **A** Axial unenhanced CT image shows a hyperdense duodenal mass (arrows) suspicious for a mass or hematoma. **B** Axial postcontrast CT image demonstrates contrast media extravasation within this structure consistent with active bleeding (dashed arrows). **C** DSA image shows contour irregularity of a branch of the gastroduodenal artery (arrow) considered the source of active bleeding. **D** Superselective coil embolization was performed to control bleeding. Follow-up imaging studies demonstrated complete regression of the hematoma with no underlying mass (not shown)

Fig. 34 59-year-old female patient with recurrent endometrial cancer invading bladder wall and sigmoid colon. She now presents with abundant hematuria. **A** Coronal post-contrast CT image shows the pelvic mass (arrows) and active bleeding within it (dashed arrow). **B** DSA image delineates the superior vesical artery as the source of bleeding (arrow). Superselective coil embolization was performed to control active bleeding (not shown)

pregnancy. Tubal ring sign, obvious live extrauterine pregnancy, or a complex extra-adrenal mass with the “ring of fire sign” on color Doppler may be helpful for diagnosis [67].

Despite its rarity, ovarian endometrioma rupture may clinically mimic functional ovarian cyst rupture (Fig. 36)

[68]. The presence of a multilocular ovarian cyst with low-level echoes on US may suggest endometrioma; however, dynamic contrast-enhanced MRI with subtraction images may be necessary to exclude underlying malignancy.

Fig. 35 Hemorrhagic ovarian cysts in two different patients. **A** 20-year-old female patient presenting with pelvic pain. Axial T2W MR image shows a cystic lesion (arrows) with fluid–fluid level (arrowhead) in the right ovary. **B** and **C** 32-year-old female patient presenting with acute onset pelvic pain. On US, a cystic lesion

(arrows) with a mural nodule (dashed arrow) was found in the right ovary. No flow signal could be detected within this nodule on color Doppler imaging. Imaging findings were found to be compatible with hemorrhagic ovarian cysts. Follow-up studies showed complete regression of the lesions (not shown)

Fig. 36 34-year-old female patient with previously known endometriomas. **A** and **B** Coronal fat-saturated T2W and axial fat-saturated T1W MR images show bilateral ovarian lesions (arrows) consistent with endometriomas. **C** The patient presented with acute onset pelvic pain three months after the first MRI examination. Axial postcontrast

CT image shows bilateral ovarian cystic lesions (arrows) and hemo-peritoneum (star). Imaging findings along with the patient's medical history were found to be representing endometrioma rupture. Surgical findings confirmed the imaging diagnosis

Fig. 37 42-year-old male patient with known neurofibromatosis type 1 presenting with acute, severe left flank pain. Axial (**A**) and coronal (**B**) postcontrast CT images demonstrate a round-shaped mass (arrows) in left retroperitoneum and associated retroperitoneal hematoma (asterisk in **B**). Also, note is made of cutaneous neurofibromas (arrowheads in **A**). Histopathological examination after surgical removal of the lesion revealed neurofibroma

Fig. 38 28-year-old male patient presenting with acute right lower quadrant pain. On US, a heterogeneous mass was found in right lower quadrant (not shown). Axial precontrast T1W (A) and T2W (B) MR images show a heterogeneous hemorrhagic lesion (arrows) in ileocaecal mesentery. Histopathological examination after surgical removal revealed desmoplastic small round cell tumor

Fig. 39 78-year-old male patient on chronic warfarin treatment presents with acute left flank pain. **A** Axial unenhanced CT image shows a large retroperitoneal hematoma (arrows) with an internal hematocrit level (arrow-head). **B** Coronal postcontrast CT image clearly demonstrates active bleeding (dashed arrows) within this hematoma. The patient was treated with transarterial embolization (not shown)

Mesenteric and retroperitoneal non-parenchymal hemorrhage

Neoplastic bleeding

Mesenteric and retroperitoneal lymph nodes are commonly affected by metastases and lymphoma. Primary mesenteric and non-parenchymal retroperitoneal neoplasms are rare entities, and most of the cases are malignant and mesenchymal in origin. Although some imaging findings, including fat, calcification, necrosis, or myxoid stroma, may provide clues for differential diagnosis, definitive diagnosis of these masses may be extremely challenging and mostly necessitate histopathological evaluation [69]. Spontaneous hemorrhage may be seen in sarcomas, neurogenic tumors, germ cell tumors, metastases, lymphoma, and desmoplastic small round cell tumors (Figs. 37, 38) [70, 71].

Fig. 40 69-year-old male patient with known abdominal aortic aneurysm presents to the emergency department with acute onset abdominal pain. Axial postcontrast CT image shows the partially thrombosed aneurysm measuring 7.5 cm in diameter. Thrombus fissuration sign (dashed arrows) and associated left retroperitoneal hematoma (arrows) are consistent with aneurysmal rupture. The patient died immediately after this scan

Non-neoplastic bleeding

Coagulopathy-related hemorrhage

Coagulopathy-related spontaneous retroperitoneal bleeding may be seen in patients on anticoagulant or antiplatelet therapy. Symptoms are mostly nonspecific, particularly in elderly patients; however, severe bleeding may manifest with hypovolemic shock [1]. On CT, a large hematoma with an internal hematocrit level is reported to be a sensitive and specific sign for coagulopathic bleeding (Fig. 39) [1]. Clinical history is usually suggestive of the diagnosis; however, an underlying mass should be sought in patients with known malignancy. Follow-up imaging is mandatory for demonstrating the interval resolution of the hematoma, as hematomas may mask the underlying mass on the initial imaging study.

Vascular causes

An abdominal aortic aneurysm may present with abdominal pain and hypovolemic shock in patients with rupture. CTA is the imaging modality of choice to detect aneurysm rupture or other alternative causes of clinical symptomatology. A crescent-shaped hyperdense area in the aneurysm wall reflecting intramural hematoma on unenhanced CT image, increasing aneurysm size, “draped aorta” sign (referring to draping of posterior wall of the aortic aneurysm to anterior surface of the adjacent vertebral body), and “thrombus fissuration sign” (referring to blood dissecting into the mural thrombus) may be indicative for an imminent aneurysm rupture. A large retroperitoneal hematoma adjacent to the aneurysm sac is almost always diagnostic for the rupture (Fig. 40) [1].

Splanchnic artery aneurysms may also be associated with rupture, with hepatic and splenic artery aneurysms being the most common. Despite being rare, spontaneous rupture of celiac and gastroduodenal artery aneurysms have also been reported in the literature [72, 73].

Conclusion

A variety of neoplastic and non-neoplastic conditions may cause spontaneously intraabdominal bleeding. Imaging findings vary depending on the source of bleeding and the underlying cause. Although imaging findings along with the patients' history usually give a clue for diagnosis, imaging-based diagnosis may be challenging, and follow-up studies or histopathological confirmation may be needed.
